Research Article

Bone biology

The adenosine diphosphate (ADP) receptor P2RY12 (purinergic receptor P2Y, G protein coupled, 12) plays a critical role in platelet aggregation, and P2RY12 inhibitors are used clinically to prevent cardiac and cerebral thrombotic events. Extracellular ADP has also been shown to increase osteoclast (OC) activity, but the role of P2RY12 in OC biology is unknown. Here, we examined the role of mouse P2RY12 in OC function. Mice lacking *P2ry12* had decreased OC activity and were partially protected from age-associated bone loss. *P2ry12*^{-/-} OCs exhibited intact differentiation markers, but diminished resorptive function. Extracellular ADP enhanced OC adhesion and resorptive activity of WT, but not *P2ry12*^{-/-} OCs. In platelets, ADP stimulation of P2RY12 resulted in GTPase Ras-related protein (RAP1) activation and subsequent $\alpha_{IIb}\beta_3$ integrin activation. Likewise, we found that ADP stimulation induced RAP1 activation in WT and integrin β_3 gene knockout (*Itgb3*^{-/-}) OCs, but its effects were substantially blunted in *P2ry12*^{-/-} OCs. In vivo, *P2ry12*^{-/-} mice were partially protected from pathologic bone loss associated with serum transfer arthritis, tumor growth in bone, and ovariectomy-induced osteoporosis: all conditions associated with increased extracellular ADP. Finally, mice treated with the clinical inhibitor of P2RY12, clopidogrel, were protected from pathologic osteolysis. These results demonstrate that P2RY12 is the primary ADP receptor in OCs and suggest that P2RY12 inhibition is a potential therapeutic target for pathologic bone loss. [...]

The adenosine diphosphate (ADP) receptor P2RY12 (purinergic receptor P2Y, G protein coupled, 12) plays a critical role in platelet aggregation, and P2RY12 inhibitors are used clinically to prevent cardiac and cerebral thrombotic events. Extracellular ADP has also been shown to increase osteoclast (OC) activity, but the role of P2RY12 in OC biology is unknown. Here, we examined the role of mouse P2RY12 in OC function. Mice lacking *P2ry12* had decreased OC activity and were partially protected from age-associated bone loss. *P2ry12*^{-/-} OCs exhibited intact differentiation markers, but diminished resorptive function. Extracellular ADP enhanced OC adhesion and resorptive activity of WT, but not *P2ry12*^{-/-}, OCs. In platelets, ADP stimulation of P2RY12 resulted in GTPase Ras-related protein (RAP1) activation and subsequent $\alpha_{IIb}\beta_3$ integrin activation. Likewise, we found that ADP stimulation induced RAP1 activation in WT and integrin β_3 gene knockout (*Itgb3*^{-/-}) OCs, but its effects were substantially blunted in *P2ry12*^{-/-} OCs. In vivo, *P2ry12*^{-/-} mice were partially protected from pathologic bone loss associated with serum transfer arthritis, tumor growth in bone, and ovariectomy-induced osteoporosis: all conditions associated with increased extracellular ADP. Finally, mice treated with the clinical inhibitor of P2RY12, clopidogrel, were protected from pathologic osteolysis. These results demonstrate that P2RY12 is the primary ADP receptor in OCs and suggest that P2RY12 inhibition is a potential therapeutic target for pathologic bone loss.

Introduction

Osteoclasts (OCs) are multinucleated myeloid lineage cells that are the principal source of bone resorptive activity (1). Enhanced OC activity, bone loss, and fractures are associated with rheumatoid arthritis, postmenopausal osteoporosis, and bone metastases (2). Modulation of osteoclastic bone resorption represents an attractive point of therapeutic intervention for the treatment of such conditions.

Numerous purinergic G-protein-coupled nucleotide receptors are expressed in the bone microenvironment (3, 4). For example, uridine diphosphate-activated (UDP-activated) P2Y6 has been reported to increase NF- κ B activation and OC survival (5), while P2Y2 (an ATP receptor) expression on osteoblasts (OBs) blocks bone mineralization (6, 7). Hoebertz et al. demonstrated that extracellular adenosine diphosphate (ADP) stimulates OC bone resorption in vitro, in part through the ADP receptor P2Y1 on OC (8); however, other ADP receptors, including purinergic receptor P2Y, G protein coupled, 12 (P2RY12), which is the target of the widely prescribed antiplatelet drug clopidogrel (Plavix), have not been evaluated for their roles in osteoclastic bone resorption.

P2RY12, initially identified as the G_{α_i} -coupled ADP receptor on platelets (9), plays a critical role in thrombus stability in vivo (10). The active metabolite of clopidogrel directly binds and irreversibly inhibits P2RY12 signaling, resulting in diminished platelet activation and aggregation, due in large part to reduced inside-out activation of the critical platelet integrin $\alpha_{IIb}\beta_3$ (11). Mice with targeted disruption of the *P2ry12* gene (*P2ry12*^{-/-}) have prolonged bleeding times associated with a decrease in platelet function (9, 10). P2RY12 signaling via G_{α_i} results in Ras-related protein (RAP1) GTPase-mediated activation of $\alpha_{IIb}\beta_3$, which is required for platelet activation and aggregation (9, 12–17). RAP1 GTPase-mediated activation of β_3 -containing integrins has been shown to be necessary for cell adhesion, spreading, and migration (13, 18–20). Importantly, β_3 integrins also play critical roles in OC formation, adhesion, and bone resorption (21). We hypothesized that ADP ligation of P2RY12 would affect OC function in part through activation of $\alpha_v\beta_3$ integrin (22–25).

P2RY12 has been shown to be biologically important in microglial cells, vascular smooth muscle cells, and brain endothelial cells (26–28) as well as in the growth of tumor cell lines (29, 30). P2RY12 is not expressed in splenic macrophages or in human alveolar macrophages and is expressed at negligible or very low levels in most other tissues (9, 31–33). Extracellular nucleotides such as

ADP/ATP are released during tissue injury, inflammation, tumor growth, and aging (34–38). ADP released during neuronal injury induces the P2RY12-dependent chemotaxis of microglia to the injury site, allowing for neuroprotective activity (31, 39, 40). We sought to examine the role of P2RY12 within the bone microenvironment during pathologic conditions associated with increases in extracellular ADP/ATP (36, 41–43).

We found that *P2ry12*^{-/-} mice exhibited decreased OC activity in vivo and were partially protected from aging-related bone loss. *P2ry12*^{-/-} macrophages displayed reduced bone resorptive activity in response to extracellular ADP. Furthermore, extracellular ADP induced RAP1 activation in a P2RY12-dependent manner. Finally, genetic or pharmacologic inhibition of P2RY12 partially protected mice from bone loss associated with arthritis, tumor growth in bone, and estrogen loss. These data suggest that antagonism of P2RY12 was sufficient to decrease OC function in vivo and decrease pathologic bone loss.

Results

P2ry12^{-/-} mice were protected from age-associated bone loss. Under non-pathologic conditions, young mice (aged 2 months) with germline loss of the ADP receptor P2RY12 (*P2ry12*^{-/-}) had no significant changes in bone mineral density (BMD), trabecular bone volume (BV/TV; Supplemental Figure 1, A–C; supplemental material available online with this article; doi:10.1172/JCI38576DS1), trabecular bone formation rate (BFR) (Supplemental Figure 1, F–H), or OC or OB numbers (Supplemental Figure 1, I–M and Supplemental Methods) compared with WT littermates. In contrast, 8-month-old *P2ry12*^{-/-} mice showed significantly increased BV/TV and BMD in the primary and secondary spongiosa of the tibia compared with WT littermate controls (Figure 1, A–C). Notably, *P2ry12*^{-/-} mice displayed trabecular bone extending into the diaphysis. Histological analyses of tibiae showed a decreased OC surface per bone surface in *P2ry12*^{-/-} mice, but no detectable change in OB number, OB surface per bone surface (Figure 1, I–M), or BFR, suggesting that decreased bone resorption predominantly contributed to the increased bone density in older *P2ry12*^{-/-} mice.

Bone turnover markers in 2- and 8-month-old mice were evaluated. In 2-month-old mice, both serum carboxy-terminal collagen crosslinks (CTX) (a marker of OC resorption) and serum N-terminal propeptide of type I procollagen (P1NP) (a marker of bone formation) were significantly decreased in *P2ry12*^{-/-} mice (Supplemental Figure 1, D and E) despite no significant difference in BV/TV, suggesting that both potential effects of P2RY12 disruption on bone resorption and formation were balanced and resulted in no significant net change in bone volume. At the 8-month time point, serum CTX was significantly decreased in *P2ry12*^{-/-} (Figure 1D), while serum P1NP was equivalent to that of WT littermates (Figure 1, E–H), consistent with the findings of increased BV/TV in *P2ry12*^{-/-} mice without significant differences in BFR. CTX and P1NP levels reflect the bone resorption and formation activities happening at a discrete point in time and may reflect transient effects of P2RY12 on both OC and on OB, whereas BV/TV by μ CT demonstrates cumulative effects on total bone, which point to defective bone resorption as a predominant consequence of *P2ry12* disruption in 8-month-old mice.

ADP enhanced ex vivo OC bone resorption primarily through the P2RY12 receptor. As *P2ry12*^{-/-} mice exhibited decreased OC activity in vivo (Figure 1, D and M), cell autonomous P2RY12 expression and function were evaluated during osteoclastogenesis.

Expression of *P2ry12* increased during ex vivo differentiation from BM macrophages (BMMs) (day 0) to Tartrate-resistant acid phosphatase-positive (TRAP⁺) OCs (day 3) and remained higher than BMMs in mature multinucleated OCs (day 5) (Figure 2A). Immunofluorescence confirmed that WT, but not *P2ry12*^{-/-}, OC cultures expressed P2RY12 (Supplemental Figure 2A). Furthermore, WT cells responded to ADP with a decrease in intracellular cAMP (Supplemental Figure 2B), but *P2ry12*^{-/-} cells or cells treated with P2RY12 inhibitor did not respond (Supplemental Figure 2, B and C, and Supplemental Methods). Under standard culture conditions, without ADP stimulation, *P2ry12*^{-/-} BMMs differentiated into multinucleated TRAP-positive OCs (Figure 2B), and no significant differences compared with WT cells in OC differentiation markers on days 1–5 (Figure 2, C–E, Supplemental Figure 3, and Supplemental Methods; all primers are listed in Supplemental Table 1), macrophage proliferation, or OC apoptosis (data not shown) were observed. Functionally, *P2ry12*^{-/-} cells exhibited decreased formation of bone resorption pits compared with WT cells (Figure 2, H–J). ADP stimulation resulted in increases in day 3 OC number and day 6 bone pit area in WT, but not *P2ry12*^{-/-}, OCs (Figure 2, F–J). We performed these experiments using BMMs from 2- and 8-month-old mice and obtained similar results. Because ADP binds both P2Y1 and P2RY12 with high efficiency and potency, with EC₅₀ values in platelet assays of 1 μ M and 60 nM, respectively (9, 44), we determine whether P2Y1 could compensate for the loss of P2RY12 expression in OCs. Expression of P2Y1 was not different between WT and *P2ry12*^{-/-} cells and was not significantly induced during OC differentiation (Supplemental Figure 4A). In both WT and *P2ry12*^{-/-} cells, ADP stimulation increased actin ring and resorption pit formation on bone (Supplemental Figure 4, B–G), suggesting that ADP signaling through P2Y1 did not exert a significant effect on OC function and that P2RY12 is a major ADP receptor in OCs. These results demonstrate that *P2ry12*^{-/-} cells exhibited intact OC differentiation, but decreased resorptive function, and that extracellular ADP can enhance osteoclastogenesis and OC function primarily through P2RY12.

P2ry12^{-/-} OCs showed impaired ADP-mediated actin ring responses and RAP1 activation. In platelets, ADP stimulation through the P2RY12 receptor acts upstream of the integrin $\alpha_{IIb}\beta_3$, resulting in platelet adhesion and aggregation (9, 44–46). Because OC adhesion via $\alpha_v\beta_3$ integrin and other integrins is necessary for actin ring formation and bone resorption (47), we hypothesized that P2RY12 ligation will act upstream of $\alpha_v\beta_3$, resulting in enhanced OC actin ring formation. ADP enhanced actin ring formation on bone in WT, but not *P2ry12*^{-/-}, cells (Figure 3, A and B). These results suggest that extracellular ADP and P2RY12 signaling can modulate actin ring response to extracellular ADP in OCs.

RAP1 GTPase in platelets is activated downstream of P2RY12-mediated activation of G $\beta\gamma$ and PI3K and is critical for inside-out activation of platelet integrin $\alpha_{IIb}\beta_3$ (14, 17, 48, 49). RAP1 also affects the activation of the related integrin $\alpha_v\beta_3$ in metastatic melanoma cells (50). We found that extracellular ADP resulted in a potent induction of activated GTP-bound RAP1 in WT pre-OCs that was blunted in *P2ry12*^{-/-} cells (Figure 3, C and D). ADP-mediated RAP1 activation was intact in integrin β_3 gene knockout (*Itgb3*^{-/-}) pre-OCs (Figure 3, C and D), suggesting that P2RY12 is upstream of β_3 integrin signaling in pre-OCs as it is in platelets. The ADP-mediated RAP1 activation in pre-OC was blocked by PI3K inhibitors (wortmannin or LY294002), but not by chelation of cal-

cium or inhibitors of adenylate cyclase or PKA (Figure 3E). Furthermore, the absence of P2RY12 did not result in significant differences in the mRNA expression of RAP1 isoforms, RAP1 guanine nucleotide exchange factors (GEFs), or GTPase-activating proteins (GAPs) during OC differentiation (Supplemental Figure 6). These data suggest that the decreased RAP1 activity in *P2ry12*^{-/-} pre-OCs was likely due to lack of signaling via P2RY12 rather than changes in the expression of genes encoding RAP1 regulatory factors.

Because M-CSF can induce PI3K activation and can rescue the adhesion/spreading defect in β_3 integrin-deficient OCs (51) and can enhance OC survival (52), we evaluated M-CSF induction of RAP1 activation in both *P2ry12*^{-/-} and β_3 integrin-null cells. Treatment of pre-OCs with M-CSF resulted in a rapid and sustained increase in RAP1 activation that was similar in WT and *Itgb3*^{-/-} pre-OCs, but was delayed in *P2ry12*^{-/-} cells (Supplemental Figure 5, A and B). ADP or M-CSF also activated RAP1 in human OCs generated from peripheral blood mononuclear cells (data not shown). In

agreement with ADP treatment (Figure 3, C–E), M-CSF-mediated RAP1 activation in pre-OCs was decreased by inhibitors of PI3K, but not by inhibitors of adenylate cyclase or PKA or by chelation of calcium (Supplemental Figure 5C). These data demonstrate that ADP- and M-CSF-mediated RAP1 activation is downstream of PI3K and may be mediated in part through P2RY12 signaling in OCs. Taken together, these results show that the P2RY12 receptor was an upstream regulator for activation of RAP1 in pre-OCs.

P2ry12^{-/-} mice had decreased arthritis-associated bone loss. Serum transfer arthritis (STA) is a well-characterized model of inflammatory bone loss that phenocopies the osteolysis associated with rheumatoid arthritis (53). In STA, serum from arthritic K/BxN mice, which contain high levels of antibodies against the self antigen glucose-6-phosphate isomerase, is injected intraperitoneally into naive mice, causing joint-centered inflammation and local OC-mediated bone erosion. WT and *P2ry12*^{-/-} mice exhibited similar clinical inflammatory responses, as measured by paw and

ankle swelling (Figure 4, A and B). However, CTX levels indicative of bone resorption were significantly decreased in *P2ry12*^{-/-} mice compared with WT (Figure 4C). Histological analysis of ankle joints showed no differences in numbers of TRAP⁺ OC per bone surface, but did show significantly decreased OC surface per bone surface (Figure 4, D–G) and a decrease in TRAP⁺ area over total tissue area in *P2ry12*^{-/-} mice. This result mirrors the in vitro findings (Figure 2, F–H) that the *P2ry12*^{-/-} OCs specifically showed decreased function without a significant change in number. Finally, WT mice with STA exhibited a significant decrease in BMD in the calcaneal bones as measured by μCT compared with *P2ry12*^{-/-} mice (Figure 4, H and I). These data demonstrate that *P2ry12*^{-/-} mice were partially protected from arthritis-associated bone loss despite the development of joint inflammation.

Genetic and pharmacologic inhibition of P2RY12 protected mice from tumor-associated bone loss. OC recruitment and activation play a critical role in tumor-associated bone loss, pathologic fracture, and pain associated with bone metastases (2). Syngeneic osteolytic B16-F10 melanoma cells were inoculated directly into 1 tibia

and PBS injected into the contralateral tibia of 8-week-old WT and *P2ry12*^{-/-} mice. The tumor burden between WT and *P2ry12*^{-/-} mice was not significantly different as measured by bioluminescence imaging (BLI) (Figure 5, A and B); however, μCT showed that WT mice displayed significant trabecular bone loss in the tumor-bearing tibiae, whereas *P2ry12*^{-/-} mice maintained bone volume equivalent to that in the saline-injected tibiae (Figure 5, C and D). Histomorphometric evaluation revealed a significant increase in OC number and surface in tumor-bearing WT tibiae compared with saline-injected tibiae, whereas OC parameters were equivalent in both *P2ry12*^{-/-} bones (Figure 5, E and F), suggesting that P2RY12 was involved in tumor-induced recruitment of OC.

We next examined the effects of pharmacologic P2RY12 inhibition in a model of bone metastasis. Clopidogrel, a specific and irreversible P2RY12 antagonist, is commonly prescribed to inhibit platelet aggregation in coronary artery disease, peripheral vascular disease, and cerebrovascular disease (11, 54). Bone metastases were established using a tumor model of intracardiac injection of the syngeneic osteolytic 4T1-GFP-FL murine

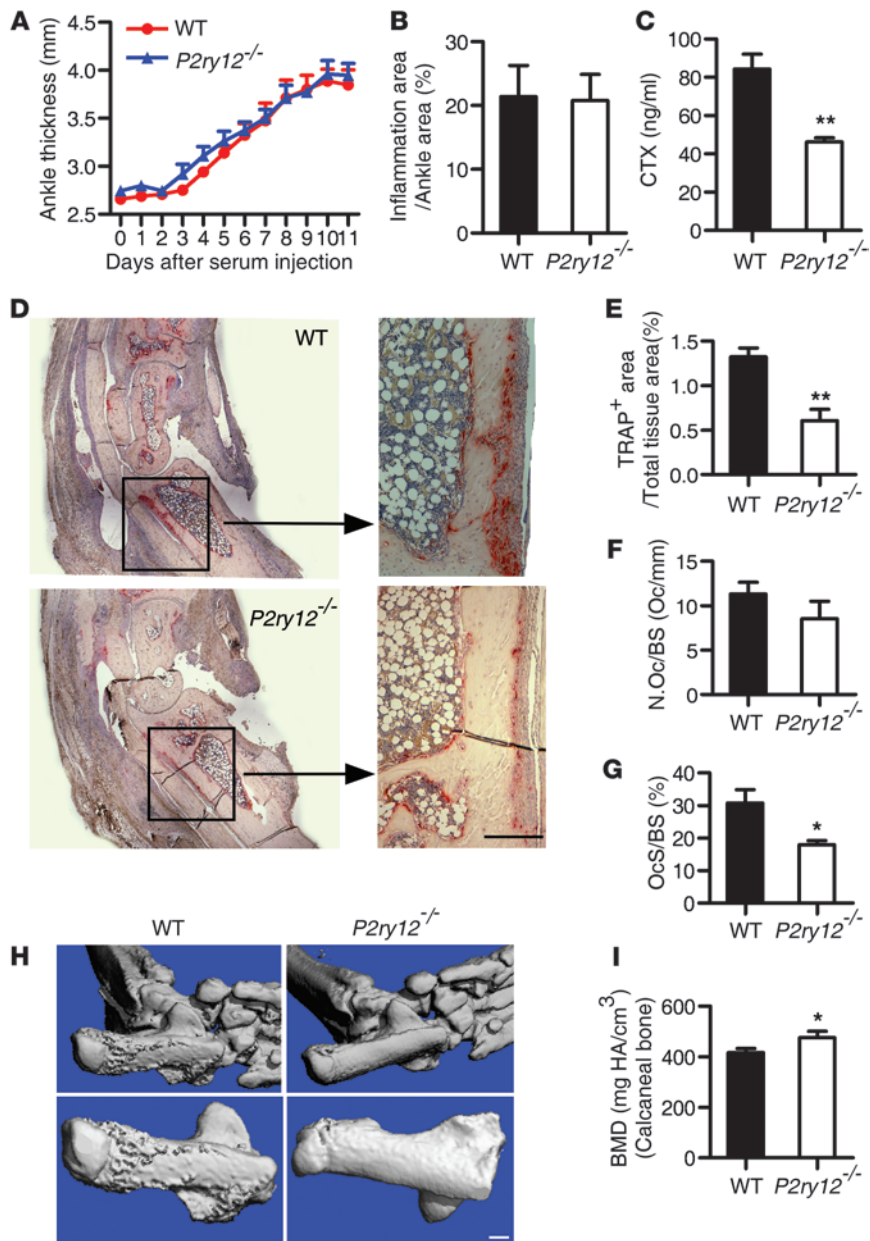

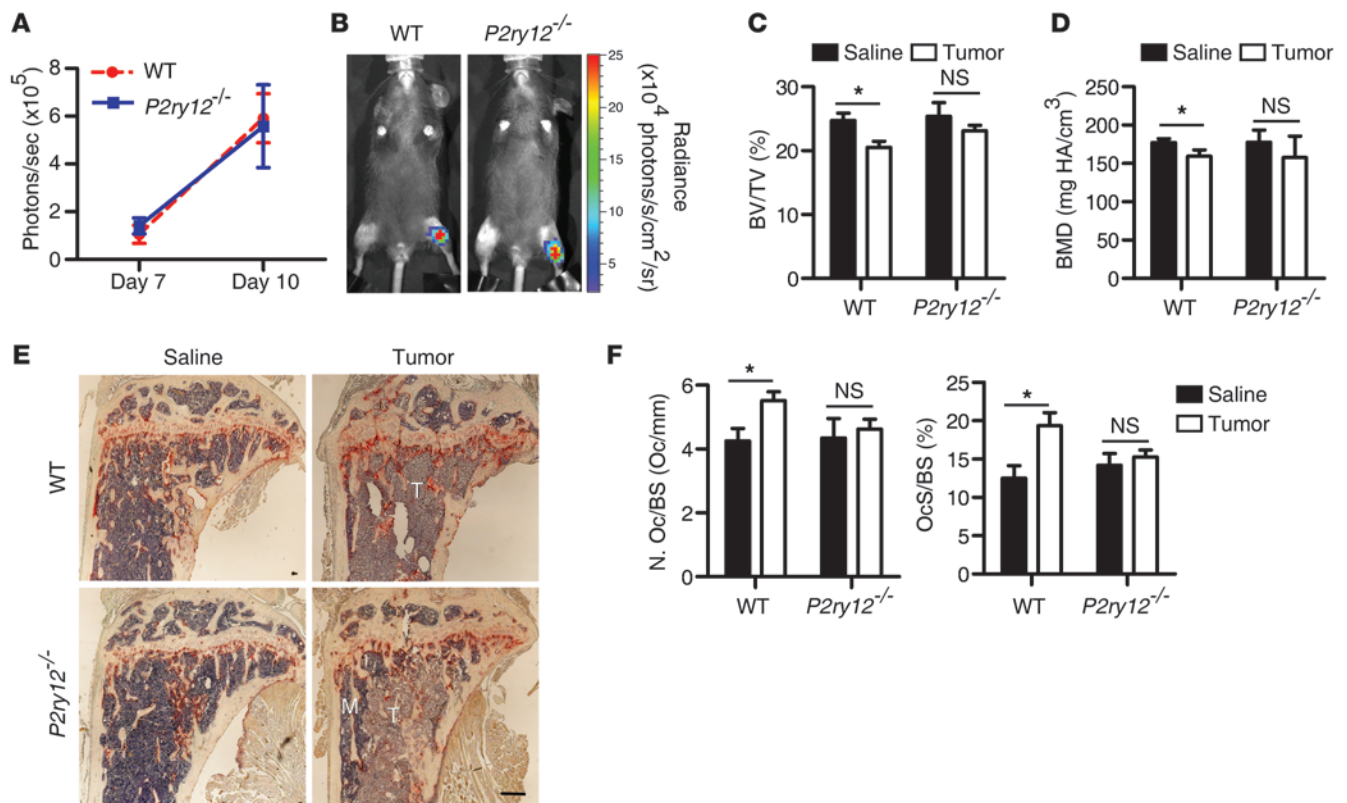

Figure 4

P2ry12^{-/-} mice had decreased arthritis-associated bone loss. STA was induced in 6-week-old WT (*n* = 8) or *P2ry12*^{-/-} (*n* = 6) mice by injection of K/BxN serum on days 0 and 2. (A) Hind paw thickness was measured bilaterally daily. (B) Inflammation area over total ankle area was determined by measuring inflammatory tissue area on hematoxylin staining of ankle tissue. (C) Serum CTX assay to measure OC activity on day 11. *n* = 5 per group. (D–F) Histological analyses of ankle with TRAP staining. Scale bar: 100 μm. Scale bar: 100 μm. mammary carcinoma cell line into immunocompetent BALB/c mice. Beginning 2 days after tumor inoculation, clopidogrel (30 mg/kg) or vehicle was administered in the drinking water for 9 days. We did not observe any change in body weight, fur ruffling, general activity, and appearance of mice that were treated with clopidogrel. As expected, mice that received clopidogrel had an increased bleeding time. Clopidogrel administration did not affect tumor burden (Figure 6, A and B), but increased tibial BV/TV and BMD compared with vehicle-treated tumor-bearing mice (Figure 6, C and D). While there was no significant decrease in OC number, clopidogrel treatment significantly reduced the OC surface per trabecular bone surface (Figure 6, E–G). Interestingly, clopidogrel treatment was associated with increased tibial BV/TV and BMD and decreased CTX in non-tumor-bearing 6-week-old WT mice (Supplemental Fig-

ure 7, A–D). Together, these results demonstrate that *P2ry12*^{-/-} mice and clopidogrel-treated WT mice were protected from tumor-induced osteolysis through effects on OCs.

P2RY12 antagonism partially protected mice from ovariectomy-induced bone loss. Because *P2ry12*^{-/-} mice were partially protected from age-associated bone loss (Figure 1), we evaluated whether the absence of P2RY12 could prevent bone loss in a model of estrogen deficiency-induced osteoporosis. Ovariectomy (OVX) was performed on *P2ry12*^{-/-} and WT littermates at 14 weeks, an age at which no significant differences in baseline BV/TV were observed. At 2 and 5 weeks after OVX, *P2ry12*^{-/-} mice had lost significantly less tibial bone mass than WT controls (Figure 7A). Serum CTX was significantly lower in *P2ry12*^{-/-} mice after OVX, whereas serum P1NP (Figure 7B) and BFR (Figure 7, C and D) were not significantly changed. In agreement, histomorphometric analysis showed that the number

**Figure 5**

Genetic inhibition of P2RY12 protected mice from tumor-associated bone loss. (A and B) 1×10^4 B16-FL tumor cells (right leg) or PBS (control, left leg) were injected directly into the tibia ($n = 6$ per group). (A and B) The tumor burden in hind limbs was measured by BLI. (C and D) BV/TV and BMD in the primary and secondary spongiosa of PBS-injected or tumor-bearing tibia were analyzed by μ CT. (E) TRAP-stained tibial sections ($\times 4$) of WT (top) and *P2ry12*^{-/-} mice (bottom) 10 days after tumor injection. T, tumor; M, marrow. TRAP⁺ staining (dark red areas) indicates OC presence. Scale bar: 300 μ m. (F) OC number and surface per bone surface in the primary and secondary spongiosa of the tibia are shown in saline-injected tibia (S) (black bars) and tumor-injected tibia (T) (white bars). Data represent mean \pm SD. $n = 6$. * $P < 0.05$.

and surface area of OCs were significantly higher in the femoral bones of WT mice compared with *P2ry12*^{-/-} mice, whereas OB number and surface area were not significantly different between WT and *P2ry12*^{-/-} mice following OVX (Figure 7, E and F). BMD did decline in *P2ry12*^{-/-} mice after OVX by day 35, but to a lesser extent than in WT mice. Together, these data suggest that *P2ry12*^{-/-} mice were partially protected from OVX-induced bone loss.

Likewise, pharmacologic inhibition of P2RY12 with clopidogrel (orally administered at 30 mg/kg/d) protected WT mice from significant OVX-induced bone loss at day 14 compared with sham surgery control (Figure 8A). At day 35, all OVX mice experienced significant bone loss compared with sham controls; however, clopidogrel-treated mice remained partially protected from OVX-mediated bone loss compared with vehicle controls (Figure 8B). At day 14, serum CTX and P1NP levels were elevated in both OVX groups compared with sham groups, indicative of increased bone turnover (Figure 8C); however, clopidogrel treatment significantly decreased CTX levels compared with vehicle, demonstrating that P2RY12 antagonism blunted osteoclastic bone resorption. While the overall extent of bone turnover was decreased by day 35 after OVX, serum CTX levels remained significantly higher in vehicle-treated mice that had undergone OVX compared with sham-treated mice, while clopidogrel treatment

decreased the CTX levels of OVX mice to a point equivalent to that of the sham control group (Figure 8C). Serum P1NP levels showed no significant difference between groups at day 35 (Figure 8C). Clopidogrel treatment blunted the increase in OC number and OC surface per bone surface observed in vehicle-treated mice following OVX at day 14 and day 35 (Supplemental Figure 8, A and B, and Figure 8, D and E). OB number and surface per bone surface were not significantly different between clopidogrel and vehicle treatment (Supplemental Figure 8, A and B). Likewise, although OVX itself did cause a decrease in BFR at day 14, but not day 35, P2RY12 antagonism with clopidogrel did not alter this response compared with vehicle (Supplemental Figure 8, C–F). In agreement with results obtained with genetic disruption of *P2ry12*, these data demonstrate that pharmacologic blockade of P2RY12 partially protected mice from OVX-induced bone loss and that the protection was predominantly from a blunting of OC-mediated resorption.

Discussion

In this report, we demonstrate what we believe is a novel role for the ADP receptor P2RY12 in the function of bone-resorbing OCs, particularly in preclinical models of pathologic bone loss associated with postmenopausal osteoporosis, rheumatoid arthritis,

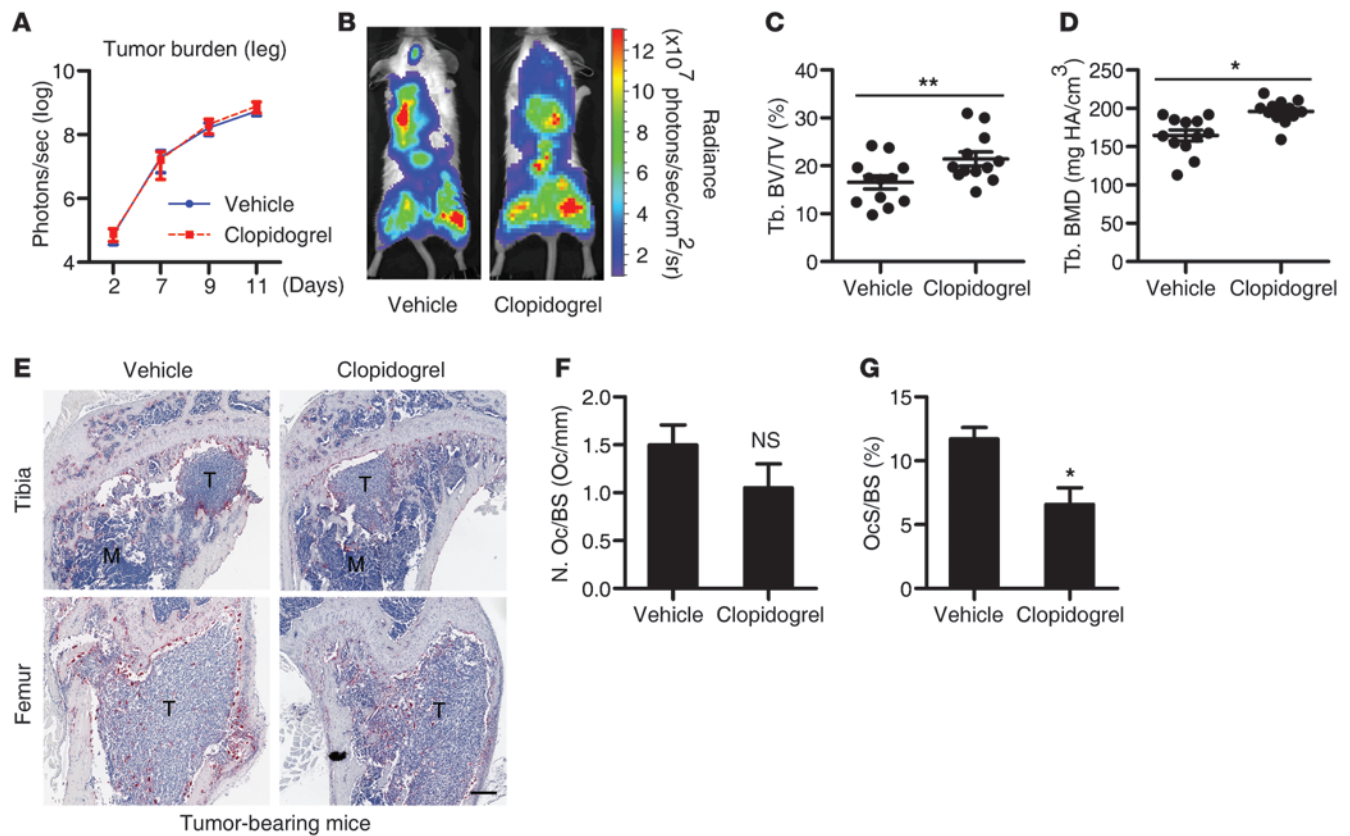

Figure 6

Pharmacologic inhibition of P2RY12 protected mice from tumor-associated bone loss. 4T1-GFP-FL tumor cells were directly injected into the left cardiac ventricle of WT Balb/c mice ($n = 12$ per group). Clopidogrel treatment (30 mg/kg/d in drinking water) was begun 2 days after tumor cell injection and continued for 9 days. (A) The tumor burden in hind limbs measured by BLI and (B) representative pictures of BLI at day 11. (C and D) BV/TV and BMD of the tibia of tumor-bearing mice at day 11 were analyzed by μ CT. (E) TRAP-stained hind limb sections at day 11 after tumor injection and vehicle or clopidogrel treatment. TRAP⁺ staining (dark red areas) indicates OC presence. Scale bar: 300 μ m. OC number and surface in the primary and secondary spongiosa of the tibia are shown (F and G). Data represent mean \pm SD. * $P < 0.05$; ** $P < 0.01$.

and bone metastases. We demonstrate that antagonism with the FDA-approved P2RY12 inhibitor, clopidogrel, decreased bone loss in murine models of osteoporosis and tumor-associated bone loss. These data suggest that clopidogrel or novel ADP and P2RY12-targeted therapies could be clinically evaluated in disease states characterized by excessive bone resorption.

The phenotypic overlap between $P2ry12^{-/-}$ and $Itgb3^{-/-}$ mice is striking. $Itgb3^{-/-}$ mice have a severe platelet aggregation defect and have increased bone mass with decreased OC function (25, 47, 55). $P2ry12^{-/-}$ mice display similar defects in platelet aggregation (10) and osteoclastic bone resorption, albeit both are milder than those of the $Itgb3^{-/-}$ mice. Similarly to $Itgb3^{-/-}$, $P2ry12^{-/-}$ mice also developed increased trabecular bone mass with aging due to impaired OC function and demonstrated protection from tumor-induced bone loss, again less severe than in the $Itgb3^{-/-}$ mice (22, 47). These results suggest that P2RY12 and β_3 integrin may lie in the same signaling pathway necessary for OC formation and function, as they do for platelet adhesion.

Decreased adhesion, actin ring formation, migration, and resorption of $Itgb3^{-/-}$ OCs have been reported (23). Adhesion is critical to the formation of actin rings in OCs and the sealing zone necessary for directional delivery of bone-resorbing enzymes and

acids (1, 47, 56). Because P2RY12 has previously been shown to play a role in adhesion in platelets and microglial cells (10, 29) and is required for microglial migration toward ADP (26, 31, 57), we evaluated its role in actin ring responses. Accordingly, we report a decrease in ADP-enhanced actin ring formation on bone by $P2ry12^{-/-}$ cells. We hypothesized that P2RY12 acts upstream of β_3 integrin through a GTPase-related mechanism in OCs similar to that in platelets and that RAP1 GTPase plays an important role in this signaling pathway. In addition to its typical $G\alpha_i$ -coupled roles, P2RY12 is known to couple to the $G\beta\gamma$ portion of the G protein heterotrimer that activates PI3K, Akt, and eventually RAP1, leading to integrin activation in platelets (12–15, 17, 58–62). We found that RAP1 activation was downstream of P2RY12 in pre-OCs and that this activation was ADP dependent.

Interestingly, β_3 integrin-null OCs had intact ADP-induced RAP1 activation, suggesting that β_3 integrins are downstream of P2RY12 signaling. P2Y1, another $G\alpha_q$ -coupled ADP receptor, is also expressed by OC lineage cells; however, our data that responses to ADP were impaired in $P2ry12^{-/-}$ but not $P2ry1^{-/-}$ cells suggest that P2RY12 is necessary for the majority of ADP-dependent RAP1 activity in OC. We cannot rule out that P2Y1 may cooperate with P2RY12 during osteoclastogenesis in situations associated with increased

Figure 7

P2ry12^{-/-} mice were partially protected from OVX-induced bone loss. OVX was performed on 14-week-old *P2ry12*^{-/-} and WT littermates ($n = 5$ per group). (A) BV/TV and BMD were measured in the primary and secondary spongiosa of the tibia of live animals *viva* CT scanning prior to and at days 14 and 35 following OVX. (B) Serum concentration of CTX and P1NP measured by ELISA. (C) Bone formation was visualized by calcein (first) and alizarin red (second) double-labeling and visualized in the trabecular bone. Representative photographs: original magnification, $\times 2.5$, scale bar: 300 μm ; original magnification, $\times 20$, scale bar: 50 μm . (D) MAR and BFR were measured. (E) TRAP-stained hind limb sections after OVX. Scale bar: 300 μm . (F) Quantification of OC and OB cells in the primary and secondary spongiosa of the femur. Data represent mean \pm SD. $n = 5$. * $P < 0.05$.

extracellular ATP/ADP. Likewise, RAP1 activation can also modulate outside-in integrin signaling, which is critical to OC function (12, 24, 63). Taken together, our data suggest that ADP-mediated RAP1 activation occurs in OC and is largely dependent on P2RY12.

In addition to RAP1, P2RY12 may also be upstream of other GTPases, such as Rac or Cdc42, which are also critical to OC function (63, 64). The potentially varying role of different purinergic receptors and RAP1 in OCs is currently under investigation. We

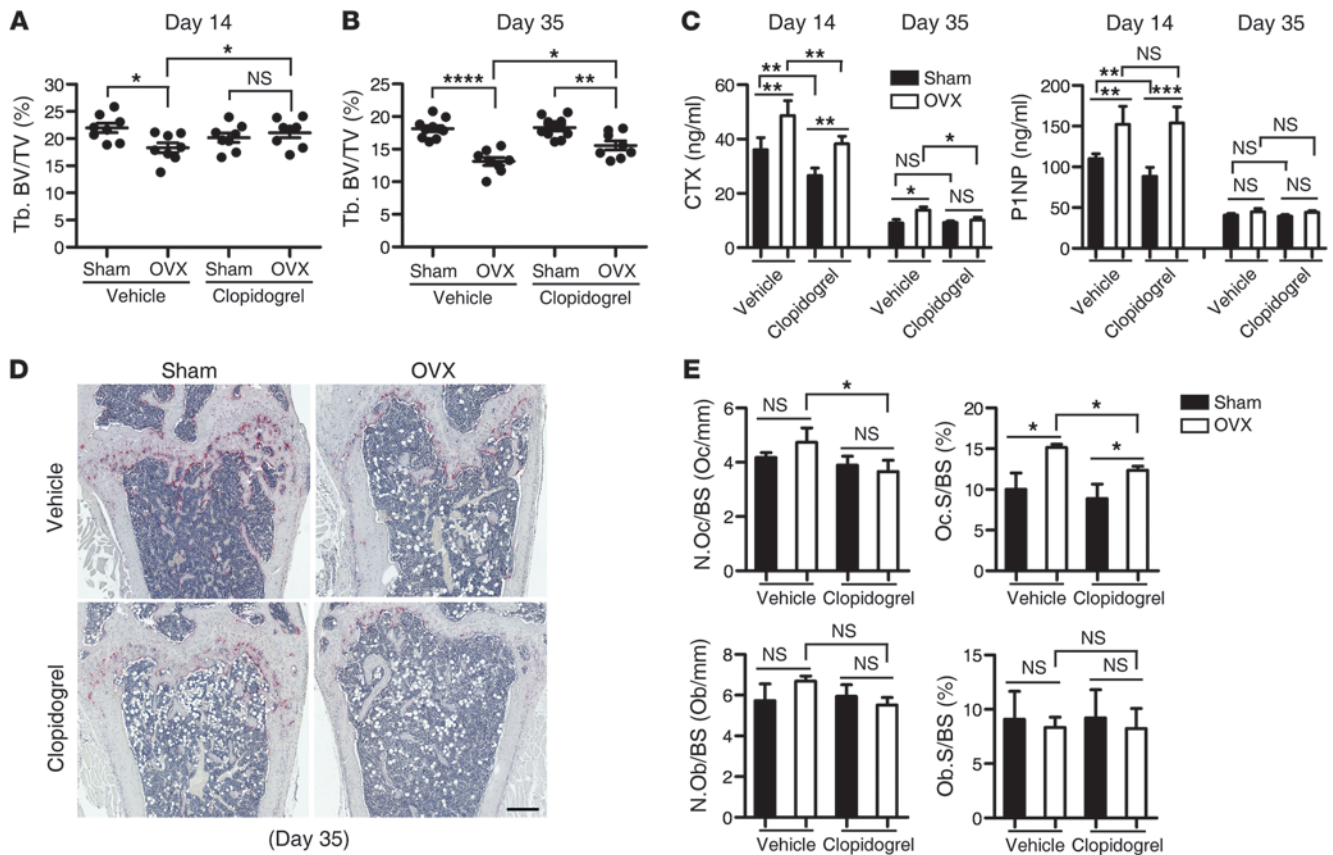

Figure 8

P2RY12 antagonism partially protected mice from OVX-induced bone loss. 14-week-old WT C57BL/6 mice underwent OVX ($n = 8$) or sham operation (sham) ($n = 10$) and were treated with clopidogrel (30 mg/kg/day) or vehicle-control in drinking water for 2 or 5 weeks. Tibias from sham-operated and OVX mice were examined by μ CT. (A and B) BV/TV in the primary and secondary spongiosa of the tibia after OVX. (C) Serum concentration of CTX and P1NP measured by ELISA. (D) TRAP-stained hind limb sections after OVX. Scale bar: 300 μ m. (E) Quantification of OC and OB cells 35 days after OVX. cannot conclude that the activation of P2RY12 yields activation of only β_3 -containing integrins, since RAP1 activity is upstream of many integrin heterodimers (12, 14, 20, 49). We propose that activation of specific integrins by P2RY12 and other purinergic receptors may exist at different phases of OC formation, such as fusion and migration; this hypothesis will be tested in future studies.

Our studies demonstrated that P2RY12 exerts its most prominent effects on bone during pathological situations in which extracellular ATP would be increased due to ongoing tissue damage and repair. Extracellular ATP can be degraded into ADP by extracellular dephosphorylating enzymes; therefore, the extracellular ADP concentration is positively correlated with extracellular ATP levels. Tumor cells are known to establish a microenvironment containing more than 100 μ M extracellular ATP, whereas ATP concentration is undetectable in healthy tissues (36). Likewise, the ATP concentration in synovial fluid from patients with rheumatoid arthritis is substantially elevated at 50 nM, but undetectable in normal joint fluids (43). Thus, under normal physiologic conditions, there is a minimal concentration of extracellular ATP in tissues and blood. Thus, the minimal effects on in vivo bone mass observed in healthy 2-month-old

P2ry12^{-/-} mice may be attributed to low extracellular ADP/ATP concentrations present under these conditions. In contrast, the increased amounts of bone remodeling and tissue repair associated with aging skeletons and organs likely release ATP, resulting in increased P2RY12 signaling, similar to that occurring in the presence of tumor or inflammatory stimuli. Under such conditions of aging (8-month-old mice) or pathology, we found that the genetic absence or pharmacological inhibition of P2RY12 blunted OC function, resulting in a preservation of bone mass. Interestingly, the administration of clopidogrel to non-tumor-bearing 6-week-old mice, a time at which bone turnover (and thus, likely extracellular ATP/ADP) is high due to skeletal growth, also increased bone volume. However, drug administration to 16-week-old mice (sham surgery group in Figure 8), a time when peak bone mass has already been mostly reached and thus turnover and ATP release would be expected to be decreased, did not affect bone mass. In experiments using both genetic and pharmacologic disruption of *P2RY12*, we observed the most protection from bone loss after OVX occurred within the first 2 weeks. We hypothesize that extracellular ADP levels are likely higher in the early time points after OVX, but it is also possible that P2RY12 disruption

could cause small sequential decreases in OB formation in the later time points. Therefore, the clinical benefit of P2RY12 inhibition or antagonism may be strongest during the early/peak time period after injury or pathology.

The dosage of clopidogrel used in the *in vivo* studies was 30 mg/kg/d, which, after species conversion, is higher than the standard 75 mg/d dosage used in humans. However, except for the expected longer bleeding time, we did not observe any negative effects on general health, such as weight, grooming behavior, and activity level. There could be indirect effects on bone of high-dose clopidogrel from effects on platelets and perhaps off-target effects. Thus, it is possible that some of the bone effects from clopidogrel may not be present or may be different at lower doses, and this will be explored in future studies.

In the disease models examined here, the effects of P2RY12 on osteolysis and bone resorption predominated, and P2RY12 genetic deletion or pharmacological inhibition consistently yielded a net increase in bone mass. However, we cannot rule out that P2RY12 may have subtle effects on bone formation and OB function. In aging mice, we did not detect differences in OB number per bone surface in *P2ry12*^{-/-} and WT mice, but there probably was an absolute increase in OB number, given the higher BV/TV in *P2ry12*^{-/-} mice. Thus, the function of individual OBs could be decreased, but this could have been balanced by the increased number to give a constant PINP. Notably, we did observe modest decreases in serum markers of both bone formation and resorption in 2-month-old *P2ry12*^{-/-} mice, although there were no changes in BMD or BFR in these young mice. This could be consistent with balanced and coupled bone formation and resorption that would have no net effect on bone volume. It is also possible that P2RY12 exerts a transient effect on OB function that may be reflected by serum PINP at a single, discrete time point, but did not result in a measurable change in the cumulative BFR measured over a period of 5 days. Such transient versus cumulative measurements of OB activity may also account for the observation of increased PINP, yet decreased BFR, observed 2 weeks following OVX (Figure 8 and Supplemental Figure 8). A detailed analysis of the vertebral and femoral bones throughout the life span of *P2ry12*^{-/-} mice will be important. Taken together, it is possible that P2RY12 may decrease OB function, but in the *in vivo* models that we evaluated, the OC dysfunction predominated, resulting in an overall increase in BV/TV. The role of P2RY12 in OBs is under intense study.

It has been reported that purinergic signaling can modulate platelet function, inflammation, and pathologic angiogenesis, which could modulate bone cell function in certain disease states (2, 22, 36, 65–68). Recent preclinical data is conflicting regarding the role of clopidogrel in inflammation both dependently and independently of its effects on platelets (36, 68). We found that in the STA model, the amount of clinical inflammation as measured by paw swelling was similar between WT and *P2ry12*^{-/-} mice. However, we cannot rule out that differences in specific inflammatory cytokines did not exist between genotypes, causing effects on pathologic osteolysis. Interestingly, β_3 integrins play a critical role in platelet function, OC function, inflammatory responses, and pathologic angiogenesis (69, 70). It is possible that some of the bone resorption effects in the disease models evaluated in our P2RY12 studies could in part be due to non-cell-autonomous effects of P2RY12 signaling on neoangiogenesis, platelet activation, and/or inflammation. It has been reported that platelet defects in a mouse model of von Willebrand disease had increased

bone mass (71). We have previously reported that mice with conditionally deleted β_3 integrin in platelets had normal bone mass despite severe platelet aggregation defects; conversely, mice with conditional deletion of β_3 integrin in myeloid/OC lineage cells had osteosclerosis and increased bone mass despite normal platelet function (72), suggesting that defective platelet function does not necessarily modulate bone mass.

Currently, there are no prospective clinical data on BMD in patients using clopidogrel. Interestingly, a population-based epidemiological study reported that the use of platelet inhibitors aspirin and dipyridamole was associated with increased risk of osteoporotic fractures, but this association was not observed with clopidogrel (73). Clinical studies evaluating the effects on bone in patients receiving clopidogrel or trials of clopidogrel in patients with excessive bone resorption are warranted to determine whether clopidogrel or other novel ADP and P2RY12-targeted therapies (11, 67, 74) could have a role as in the treatment of disease states characterized by excessive bone resorption. We propose that P2RY12 targeting would likely only have effects on bone during localized increases in extracellular ADP that can occur during tissue damage, inflammation, and cancer, with little effects on normal systemic bone turnover. Our data suggest that antagonism of the ADP receptor, P2RY12, using currently available drugs could represent a new approach to preventing pathologic bone loss.

Methods

Mice. WT, *P2ry12*^{-/-} (10), and *Itgb3*^{-/-} mice (75) on a pure C57BL/6 background were housed under pathogen-free conditions according to the guidelines of the Division of Comparative Medicine, Washington University School of Medicine. Unless noted, all mice were used at 6 to 10 weeks of age. *P2ry1*^{-/-} BM cells (BMCs) were provided by Christian Gacher (Université de Strasbourg, Strasbourg, France) (76).

Micro-computed tomography. Tibial metaphyses were scanned by micro-computed tomography (μ CT) (μ CT-40; Scanco Medical). The trabecular region from forty 2D slices (0.8 mm) in the primary and secondary spongiosa of the tibia was selected using contours inside the cortical shell on each 2D image, with the growth plate as a marker to determine a consistent location to start analysis. A 3D cubical voxel model of bone was built, and calculations were made for BV/TV and apparent BMD (calibrated against a hydroxyapatite phantom). A threshold of 300 (out of 1,000) was used to differentiate trabecular bone from nonbone.

Serum CTX and PINP assays. CTX and PINP were measured in fasting serum using ELISA systems (Immunodiagnostic Systems Inc.).

OC culture assay. To generate primary BMMs, whole BM was extracted from the femurs and tibias of mice and plated in petri dishes in α -MEM medium containing 10% fetal bovine serum and M-CSF-containing CMG-14-12 cell culture supernatant (50 ng/ml). For OC differentiation assays, BMMs were plated at 2×10^4 per well in 48-well cell culture plates and fed daily with osteoclastogenic medium (α -MEM containing 10% FBS, CMG-14-12 supernatant [50 ng/ml], and GST-RANKL [50 ng/ml]) for 3 to 6 days, as previously described (77). Then, 1 μ M ADP (Sigma-Aldrich) was added daily to cultures as indicated. TRAP staining was performed according to the manufacturer's instructions (Sigma-Aldrich). The number of TRAP⁺ OCs with 3 or more nuclei were counted using ImageJ software (NCBI).

In vitro bone resorption assay. Bone resorption assays were performed as previously described (77). For actin ring staining, cells were cultured on bovine bone slices in osteoclastogenic medium with or without 1 μ M ADP for 6 days. Cells were fixed in 4% paraformaldehyde, permeabilized in 0.1% Triton X-100, rinsed in PBS, and immunostained with Alexa Fluor 488 phalloidin (Molecule Probes) or Rhodamine-phalloidin

(Invitrogen). To quantify resorption lacunae, cells were removed from bone slices, and bone slices were incubated with peroxidase-conjugated wheat germ agglutinin (WGA) (Sigma-Aldrich) and stained with 3,3'-diaminobenzidine (Sigma-Aldrich). Resorption area was determined from five 4× fields using BioquantOsteo software (Bioquant) by an operator blinded to genotype.

RAP1 pull down assays and Western blotting. BMMs derived from 2-month-old mice and OCs were cultured as above; day 3 OCs (pre-OCs) were used for experiments. After ADP (0–1 μm) or CMG-14-12 supernatant (100 ng/ml) treatment, cells were washed in PBS and harvested into Tris Lysis Buffer (TLB) (50 mM Tris-HCl, pH 7.4, 500 mM NaCl, 1% NP40, 2.5 mM MgCl₂, and 10% glycerol) plus 1% Mammalian Protease Inhibitor Cocktail (Sigma-Aldrich). As indicated, cells were also treated with PI3K inhibitor (wortmannin or LY294002), inhibitor for adenylate cyclase (ddADO), or PKA (H89), or by chelation of calcium (BAPTA). A sample of the supernatant was incubated with Ral GDS-RBD-labeled Agarose Beads (Upstate Biotechnology) for 45 minutes at 4°C. After washing, bound RAP1-GTP was released from the beads by boiling in 2× Laemmli reducing sample buffer. Western blotting was used to detect total RAP1 and RAP1-GTP using rabbit anti-RAP1a/1b antibody (Cell Signaling Technology Inc.), secondary HRP-conjugated goat anti-rabbit IgG (Calbiochem), and chemiluminescent substrates for HRP (SuperSignal; Thermo Scientific). Densitometry, where appropriate, was performed using Quantity One software ver. 4.5.1 (Bio-Rad).

STA. The STA model was described previously (53). Briefly, 6-week-old WT and *P2ry12*^{-/-} mice were used in this model; arthritis was induced by injection of serum from arthritic K/BxN mice on days 0 and 2, and hind paw thickness was measured bilaterally every day (*n* = 5 per group). On day 11, hind limbs were fixed and scanned by μCT. Histologic sections of the hind paw were also analyzed as in *Bone histomorphometry*. Inflammation area over total ankle area was determined by measuring inflammatory tissue area on H&E staining of ankle tissue. TRAP⁺ area over total tissue area, OC number, and OC surface per bone surface were measured by Bioquant Osteo software (Bioquant Image Analysis Corp.) on TRAP-stained slices of ankle tissue.

Image acquisition. Images of cells and isolated tibial, femoral, and calcaneal bones were taken with a Nikon Eclipse TE300 inverted microscope connected to a Magnafire camera model S99802 (Optronics). The ×4 Nikon lens with numerical aperture 0.13, the ×10 Nikon lens with numerical aperture 0.30, or the ×40 Nikon lens with numerical aperture 0.60 was used.

Bone histomorphometry. Mouse hind limbs or tibias/femurs were fixed in 10% formalin for 24 hours and decalcified in 14% EDTA solution for 2 weeks (tibia and femur) or 3 weeks (hind limbs with soft tissue). Paraffin-embedded sections were stained with H&E for OB parameter analysis or stained with TRAP for OC parameter analysis within the primary and secondary spongiosa. Sections were analyzed by a blinded operator according to a standard protocol using Bioquant Osteo V7 10.10 (Bioquant Image Analysis Corp.).

Tumor and bone metastasis models. The B16-F10 C57BL/6 murine melanoma cell line (ATCC) was modified to express firefly luciferase (B16-FL) as described (77). For intratibial injections, 1 × 10⁴ B16-FL cells in 50 μl PBS were injected into the right tibia, and PBS (50 μl) was injected into the left tibia as an internal control (77). At day 9, tibias were fixed and decalcified for histologic sections.

For intracardiac injections, the left ventricular chambers of 6-week-old female Balb/c mice were inoculated with 10⁵ 4T1 BALB/c triple-negative murine breast cancer cells labeled with GFP-firefly luciferase gene (4T1-GFP-FL) (78) in 50 μl PBS as previously described (77). BLI was performed on days 2, 7, 9, and 11 after inoculation. Treatment with clopidogrel (30 mg/kg/d in drinking water) was begun 2 days after

tumor cell injection. Mice underwent blinded necropsy on day 11 after tumor cell injection, and tibias were fixed and analyzed by μCT. Mice were discarded from the final analysis when the animal died before day 11 or necropsy showed a large mediastinal tumor indicative of injection of tumor cells into the chest cavity. In order to have sufficient remaining trabecular bone for histomorphometry analysis, all data were analyzed from the tibia where areas of non-tumor-invaded bone were still present, since tumor burden is often higher in femurs, likely due to increased marrow space.

BLI. For BLI of live animals, previously described mice were injected intraperitoneally with 150 μg/g D-luciferin (Biosynth) in PBS, anesthetized with 2.5% isoflurane, and imaged with a charge-coupled device (CCD) camera-based BLI system (IVIS 100; Caliper; exposure time 1–60 seconds, binning 8, field of view 12, f/stop 1, open filter, anterior side). Signal was displayed as photons/s/cm²/sr (79). Regions of interest (ROI) were defined manually around the legs using Living Image and IgorPro Software (Version 2.50).

OVX. OVX or sham surgeries were performed as described in ref. 80 with the following modifications: 14-week-old female C57BL/6 mice or *P2ry12*^{-/-} mice were anesthetized using 2% isoflurane; ovaries were exposed through an abdominal approach and removed by cauterization. The peritoneum and skin were sutured separately. Pain was managed by subcutaneous injection of 0.075 mg/kg bupernorphine followed by 1:30 dilution of children's liquid pain reliever (32 mg acetaminophen/ml) in the drinking water for 2 days. Clopidogrel treatment (30 mg/kg/d in drinking water) was begun 2 days after OVX.

Statistics. Data are shown as mean ± SD unless noted otherwise. All experiments were analyzed using 2-tailed unpaired Student's *t* test for 2 groups or 1-way ANOVA with Bonferroni's post-hoc test for 3 or more groups by Prism (GraphPad Software). *P* < 0.05 was considered significant.

Study approval. The study protocols were approved by the Washington University Animal Studies Committee.

Acknowledgments

The authors wish to thank Steven Teitelbaum, F. Patrick Ross, Roberta Faccio, Haibo Zhao, Thomas Baranski, Michael Tomasson, Tiffany Foulks, and Viviana Cremasco for their valuable expert suggestions and criticism.
